early Holocene atmospheric and ocean temperatures in the AP region were higher than those measured in recent decades. However, if IPCC predictions of increased atmospheric temperatures in the coming decades continue to apply to the AP we can expect that its ice shelves will continue to retreat (Hodgson et al., 2006).

Marine sediment cores collected from the northeast of South Georgia, the Scotia Sea and down both sides of the AP are also revealing spatial and temporal changes in oceanographic variables along the AP transect. Initial results, focussing on changes in sea-ice extent, suggest an early retreat of summer sea ice across the Scotia Sea, with the average summer sea-ice margin being close to its Holocene position before 21 cal kyr BP. In contrast, the winter sea-ice limit was stable north of the Falkland Trough until at least 19 cal kyr BP (Allen et al., 2005). This is similar to records from the eastern Atlantic and Indian sectors of the Southern Ocean that also document a pre-LGM summer sea-ice maximum and early retreat to a near-modern extent by the LGM (Crosta et al., 1998; Gersonde et al., 2005). This means that the seasonal area of sea-ice growth and decay would have been more than double that of today’s Southern Ocean, producing a much larger expanse of seasonally open-water than most models suggest. The associated impacts on Southern Hemisphere albedo and ocean-atmosphere energy transfers would have had a profound influence on feedback-dynamics during the glacial transition and are being further explored.

Our ice, lake and marine records have been selected for their high resolution and to facilitate detailed time-series analyses to determine the timing and phasing of climate events through the Holocene. Our activities also compliment a recent intensification of paleoecological research in southernmost South America and to the new and exciting ice core records from central East Antarctica (produced) and West Antarctica (in progress). Together with records from collaborating groups, these activities should give us a comprehensive view of how the climate system in the AP has behaved, and how it is linked to global climate via CO₂ orbital forcing, major modes of atmospheric circulation, ocean circulation and sea ice.

The Lake Malawi Scientific Drilling Project

Christopher A. Scholz
Department of Earth Sciences, Syracuse University, USA; cascholz@syr.edu

In 2005, an international team of researchers undertook an ambitious plan to drill two sites in Lake Malawi (9° -14°S), in water depths of 592 and 359 m in the central and northern basins of the lake. Lake Malawi is located in the southern end of the western branch of the East African Rift System (Fig. 1, inset). It extends along more than 550 km of the rift valley, and with a depth of 700 m, it is the second-deepest lake in Africa. Along with Lake Tanganyika, Lake Malawi contains one of the longest high-resolution paleoclimate records of the continental tropics.

The primary objective was to obtain a continuous, high-resolution (annual-decadal) record of past climates in the continental tropics, and to then determine if tropical African climate responded to changes in low-latitude precessional insolation (23-19 kyr), or to high-latitude ice volume (100 kyr and 41 kyr) forcing, during the late Pleistocene.

The project initially faced very difficult engineering and logistical challenges. A 160 ft fuel barge was used as the drilling platform, which was stabilized by a portable dynamic positioning system designed to maintain the position of the barge for weeks at a time (Fig. 1). The drilling operation involved 26 personnel aboard the
Past Climate Dynamics: A Southern Perspective

Varves have been shown to be varves, and thus annual records may be recovered from many discrete intervals over the cored interval. Prior to drilling, preliminary studies were undertaken including detailed analyses of short cores and extensive seismic reflection datasets (Fig. 2). The earlier studies suggested that the climate system of this southern hemisphere tropical site has linkages to high-latitude climate, but evidence of very high-amplitude lake-level shifts also implied possible orbital control of effective moisture in the lake’s vast catchment. The first results from drill core analyses indicate that on two occasions, between 135 and 75 kyr, water levels dropped to more than 550 m below modern levels. Lake level then increased and stabilized after 70 kyr, reaching modern levels sometime after 60 kyr (Scholz et al., 2007). Similar findings are observed in data from Lake Tanganyika and Lake Bosumtwi (West Africa). Surprisingly, the early late-Pleistocene lake-level lowstands and megadroughts were much more severe than the low lake stages observed during the Last Glacial Maximum in all three of these tropical lakes. The termination of the high climate variability interval that included the megadroughts may have played an important role in the final African exodus and population expansion of Early Modern Humans (Scholz et al., 2007).
