Deep-ocean flow-speed changes linked to the NAO through Labrador Sea convection

Karin P. Boessenkool, I.R. Hall, H. Elderfield and I. Yashayaev

The Atlantic Meridional Overturning Circulation (AMOC) is important for the stability of the climate of northwest Europe, with models demonstrating that alterations in its strength and structure can lead to abrupt climate change (Rahmstorf, 2002). The Gulf Stream and its extension, the North Atlantic Current (Fig. 1a), are surface elements of the MOC while North Atlantic Deep Water (NADW) is its main southbound constituent. The densest components of NADW are formed in the Nordic Seas where cold, salty water sinks. Iceland-Scotland Overflow Water (ISOW) and Denmark Strait Overflow Water (DSOW) jointly comprise the cold, dense overflows from the Nordic Seas across the Greenland-Scotland Ridge (GSR). The strength of the GSR overflows seems to be modulated by the North Atlantic Oscillation (NAO) (e.g., Bia toc et al., 2003), which is the dominant mode of atmospheric variability in the North Atlantic sector. As ISOW descends into the deep North Atlantic, its volume nearly triples due to entrainment of salty, warm Atlantic subpolar-mode water (SPMW; Fig. 2) and fresher Labrador Sea Water (LSW; Hansen and Østerhus, 2000). ISOW freshened (Dickson et al., 2002) and the overflow weakened (Hansen et al., 2001) during the last four decades of the 20th century. However, it is not known if these changes fall within the natural variability of the system.

**ISOW flow speed changes and the NAO**

We reconstructed past changes in the near-bottom flow speed of ISOW using the paleocurrent proxy ‘ sortable’ silt mean grain size (SS)—the mean grain size of the 10-63 µm terrigenous silt fraction (McCave et al., 1995). The flow of ISOW has built up extensive sediment drifts, such as the Gardar Drift along the eastern slope of Reykjanes Ridge, that are well suited for this method (Bi anthi and McCave, 2000). Sediment box core RAPID-21-12B (Fig. 1), recovered from the southern Gardar Drift, was dated using the 210Pb method (Boes senkool et al., 2007). We constructed a continuous SS record through the period 1770-2004 AD, where each sample represents an integrated signal of 2.2 ± 0.2 yr. The decadal trends shown in Figure 1b reflect changes in ISOW vigor as it passed over the eastern flank of Reykjanes Ridge (ISOWRR, Boessenkool et al., 2007).

The NAO is usually expressed as an index of the normalized sea-level pressure difference between the Azores High and Iceland Low pressure areas. To explore the interrelation between ISOW flow speed and the NAO, the winter (December-March) index of the NAO (Jones et al., 1997) was smoothed using a 7-year filter because the ocean’s inertia acts as a natural filter for higher-frequency changes occurring in the atmosphere. Statistical analysis (cf. Mudelsee, 2003) revealed a significant, inverse linear correlation between the SS record and the NAO index on decadal timescales (Boessenkool et al., 2007), with the strongest correlation ($r = -0.42$) for the period 1885-2004 AD (n=55). It suggests that the flow of ISOWRR has been persistently stronger during low NAO index phases.

**Hydrographic timeseries and deep-flow speed**

To explain this relation, we first compared flow-speed variations and the NAO index with hydrographic time series of ISOW$_{RR}$. We focused on the period of the pronounced NAO reversal, from an extremely negative index state in the 1960’s to dominantly positive values through the 1990’s (Fig. 1b), where the SS record (Fig. 1c) declines significantly, suggesting a marked slowdown of ISOW$_{RR}$ flow. Parallel patterns in the SS record and two ISOW salinity time series (Fig. 1c) suggest that changes in ISOW flow speed and salinity are coordinated. Furthermore, consideration of oceanographic changes between the two NAO extremes showed (1) a density decrease of ISOW$_{RR}$ (Fig. 2), and (2) a ~25% reduction in volume transport of total deep southward flow over the eastern Reykjanes Ridge (Boessenkool et al., 2007), similar to the decrease in ISOW passing through the Charlie-Gibbs Fracture Zone (CGFZ, 1a; Saunders, 1994). It is likely that variations in ISOW$_{RR}$ vigor are caused by changes in any of its constituents: ISOW proper, SPMW and LSW. Over the four decades spanning the NAO reversal, all three components freshened (Dickson et al., 2002; Curry and Mauritzen, 2005; Lazier et al., 2002). However, while ISOW and SPMW became less dense, LSW not only reached its freshest but also its coldest and densest state ever recorded in 1993/94 (Dickson et al., 1996; Lazier et al., 2002), after a number of high-NAO-index winters (1990-94) led to exceptionally vigorous and deep convection in the Labrador Sea. The unprece-
dent large, dense body of LSW invaded the intermediate depths of the subpolar North Atlantic within 2-5 years (Fig. 2b; Yashayaev et al., 2007). By contrast, LSW production, density and export were greatly reduced during the 1960’s (Fig. 2a), after several low-NAO-index winters (Dickson et al., 2002).

Some model studies suggest convective changes in the Labrador Sea may be more important in the production of NADW than variations in the GSR overflows (Cheng and Rhines, 2004; Eden and Jung, 2001); particularly, the modeled overflows weaken when LSW formation intensifies. We suggest that the larger volume of denser and fresher LSW that built up over the NAO transition played a major role in slowing the deep flow of ISOW RR. It is, therefore, difficult to ascribe the observed flow speed changes to a single cause. Nevertheless, our data suggest that the NAO influences deep-ocean current speeds in the North Atlantic, and that LSW could rapidly transfer NAO forcing to the deep ocean.

Figure 2: Salinity and density profiles on trans-Atlantic hydrographic sections (Fig. 1a; section AR7E, World Ocean Circulation Experiment) for (a) 1966 and (b) 1994. Red circles indicate (projected) core location. Yellow and magenta contours are isopycnals (kg m⁻³) indicating characteristic densities of intermediate (yellow, LSW) and deep (magenta, ISOW and DSOW) waters. Figure modified from Boessenkool et al., 2007.

Implications for monitoring future AMOC stability

Most hydrographic time series started in the 1960’s. Although pre-1960’s salinity data are sparse, they are again closely mirrored by the SS record (Fig. 1c). Only the extreme values for 1961 and 2000 in the ISOW RR flow speed record lie outside the 20 range of the 230-year record. Thus, most of the recent changes in ISOW RR flow cannot be distinguished from natural variability in the deep flow. Average values for both ISOW RR flow speed and salinity time series were recorded during the mid-1970’s, suggesting that this period, coupled with the 1960-2000 range, might provide useful reference levels for future oceanographic changes.

In conclusion, our paleocurrent-speed record suggests that decadal-scale changes in ISOW RR vigor during the past 230 years are significantly, inversely correlated with the NAO index. Property changes of ISOW RR constituents have previously been attributed to NAO forcing. Many of them theoretically work in the same direction, either slowing down or speeding up ISOW RR flow. It is, therefore, difficult to ascribe the observed flow speed changes to a single cause. Nevertheless, our data suggest that the NAO influences deep-ocean current speeds in the North Atlantic, and that LSW could rapidly transfer NAO forcing to the deep ocean.

Note

Data will be available from the NOAA Paleoclimatology website at: www.ncdc.noaa.gov/paleo/paleo.html

Acknowledgements

We thank H. Medley for laboratory assistance. M. Bersch kindly supplied hydrographic data. We are grateful to the master, officers, crew and scientific party of RRS Charles Darwin cruise CD159. This work was supported by the U.K. Natural Environment Research Council Rapid Climate Change Programme.
