FTIRS analysis of small sediment quantities can provide fast, inexpensive and high-resolution records of organic and inorganic carbon, nitrogen and biogenic silica that are essential for detailed paleoclimate and environmental reconstructions in long sediment records.

Continuous paleoclimate records from the continental realm covering several climatic cycles are increasingly recognized as important archives of environmental responses to climatic change. Given anthropogenic global warming, this information is particularly crucial for the understanding of natural climate variability. Over the past decade, the recovery of long sedimentary records from terrestrial sites and, in particular, large and ancient lakes, has been made possible by the International Continental Drilling Program (ICDP) and associated partners. The most recent example is Lake El’gygytgyn, where the longest (>300 m, 3.6 Ma) and probably most continuous terrestrial paleoclimate archive has been recovered during the spring 2009 deep drilling campaign. In order to extract information on climatic and environmental change from these long records at a high temporal resolution, fast, cost-efficient and, preferably, non-destructive methods are required. X-ray fluorescence scanners and multi-sensor core loggers can provide such highly resolved, qualitative and semi-quantitative information on the inorganic geochemistry, mineralogy, and magnetic properties of sediments. Non-destructive methods providing quantitative information on biogeochemical properties, however, have not been available until present. Within the initial Lake El’gygytgyn deep drilling project, and preliminary studies for potential deep drilling projects at Lake Ohrid and Pingualuit Crater Lake, we tested the potential of Fourier transform infrared spectroscopy (FTIRS) as analytical method for the quantitative determination of biogeochemical properties. The great potential of the FTIRS technique comes from the large amount of information on mineralogic and organic substances provided by the FTIRS spectra. Most importantly, it is a rapid, cost-saving technique, which only requires very small amounts (0.01g dry weight) of sample material.

Analytical background and principles of FTIRS

The basic principle of the FTIRS technique is that infrared radiation stimulates molecular vibrations and, as a consequence of the quantum mechanical behavior, this radiation is absorbed at specific wavenumbers. Major changes in organic and inorganic properties present in sediment can therefore be qualitatively identified from the FTIRS spectra. For example, the band
between 2850 and 2950 cm$^{-1}$ is due to C-H vibrations in -CH$_3$, -CH$_2$, and –CH groups of organic compounds. Bands centered on 1715 cm$^{-1}$ are assigned to the stretching vibration of the –C=O group of fatty acids (Mecozzi and Pietrantonio, 2006). Carbonate in calcite minerals has important C-O molecular vibrations around 710, 875, 1425, 1460, 1800 and 2500 cm$^{-1}$ (White, 1974; Mecozzi and Pietrantonio, 2006; Rosén et al., 2009) and SiO in biogenic silica has an important absorbance maximum at 1100 cm$^{-1}$ (Stehfest et al., 2005; Rosén et al., 2009). FTIRS can thus provide information on a wide range of organic and minerogenic components, e.g., carbohydrates, humic substances, silicates and carbonates (Calace et al., 1999; Stehfest et al., 2005; Mecozzi and Pietrantonio, 2006; Rosén et al., 2009). FTIRS can thus provide information on a wide range of organic and minerogenic components, e.g., carbohydrates, humic substances, silicates and carbonates (Calace et al., 1999; Stehfest et al., 2005; Mecozzi and Pietrantonio, 2006; Rosén et al., 2009).

Absorbance in FTIR spectra from the mid-infrared region directly relates to the concentration of specific compounds, and thus many organic and minerogenic sedimentary components can also be quantified by their own “fingerprint-like” infrared spectra. To obtain quantitative information using FTIRS, concentrations of sedimentary components measured by conventional techniques are regressed against the FTIR spectra using partial least square regression (PLS). A PLS loading plot can be compared with reference spectra of the pure component of interest, thus ensuring that the correct wavenumbers are used by the model (Rosén et al., 2009). So far, quantitative models for total organic carbon (TOC), total inorganic carbon (TIC), total nitrogen (TN), and biogenic silica (BSi) have been developed and successfully applied to lake sediments from different climatic settings (Vogel et al., 2008; Rosén et al., 2009). These promising results confirm the great potential of FTIRS as a powerful tool in high-resolution, multi-proxy paleolimnological studies.

Potential, limitations and examples

Interpretation of FTIR spectra can be complicated by overlapping peaks and bands that can result from the mixture of a large number of components in lake sediments. As a consequence, it is most likely that only the most common components or those with narrow absorption bands can be assessed quantitatively using FTIRS. For longer sediment records to be analyzed, for example those of ICDP deep drilling projects, with cores exceeding several hundred meters in length, the creation of a site-specific internal calibration is recommended. This technique has already been

Figure 1: 2D plot of FTIR spectra from sediment core Lz1120 (Lake Ohrid, Albania/Macedonia). Wavenumbers are displayed on the x-axis, sediment depths are shown on the y-axis, and absorbance is indicated by a color chart with red/violet indicating highest and blue indicating lowest absorbance. Absorption bands for C-H stretching in organic carbon, C-O stretching in inorganic carbon and Si-O stretching in silica are indicated in the graph. The sediments show large changes within these components (from Vogel et al., 2008, with permission from Springer Verlag).

Figure 2: Downcore plot of total organic carbon (TOC), total nitrogen (TN) and biogenic silica (BSi) within sediment core PG1351 from Lake El’gygytgyn (northeastern Siberia), measured with conventional (orange line) and inferred (black line) techniques using FTIRS. Due to the lower number of conventionally measured BSi concentrations, these samples are identified by crosses (from Vogel et al., 2008, with permission from Springer Verlag).
applied to sediments of lakes El’gygytgyn, Siberia, Ohrid, Albania/Macedonia and Pingualuit, Canada (Vogel et al., 2008; Rosén et al., 2009). As shown in Figure 2, FTIRS-inferred TOC, TN and BSI are plotted against values using conventional techniques and the results show a close agreement (Vogel et al., 2008). Although the results look promising, we should keep in mind that this quantitative approach has only been tested on a few lakes and we therefore recommend that some FTIRS-inferred values are cross-checked against "conventionally" measured values. With respect to the Lake El’gygytgyn sediment record, FTIRS-inferred BSI concentrations have become one of the most important proxy indicators for assessing past climatic and environmental change at fairly high-resolution back to 340 ka. In addition to quantitative assessment of biogeochemical properties, FTIRS has also been used to assess past changes in tree line and to infer lake water TOC (Rosén and Persson, 2006). After samples have been freeze-dried, ground and mixed with potassium bromide, up to 300 samples per day can be analyzed using FTIRS, which is about ten times faster compared to leaching methods (e.g., Müller and Schneider, 1993) commonly used for the determination of BSI concentrations, clearly demonstrating the advantages of FTIRS over conventional methods.

Other research areas and future applications

FTIRS is widely used in both research and industry as a reliable technique for the measurement and quality control of food and pharmaceuticals. The technique is also used in soil science to complete studies on molecular-level processes at mineral, organic, and bacterial surfaces that influence the biogeochemical cycles of elements (Schnürer et al., 2006). In recent years, the development of the FTIRS microscopy technique makes it also possible to assess specific spectra of components identified with the help of a microscope. One such example is demonstrated in Rosén et al. (2009) where spectra from single diatom valves were assessed. Thanks to the continuous technological development and improvement of FTIR spectroscopy, potential applications of the technique also continue to increase. Considering the variety of applications presented in this newsletter, we encourage more researchers to further develop this method for potential application in marine/ocean or lake sediment science.

Current stable isotope techniques permit the development of new approaches for reconstructing past climate and aquatic food webs based on chitinous invertebrate fossils from lake sediments.

Chitin is one of the most abundant macromolecules in the biosphere. It can be found in the cuticles of most invertebrates (Cauchie, 2002) and especially in exoskeletons of insects and crustaceans, where elastic chitin rods are typically embedded in and cross-linked with a matrix of proteins (Nation, 2002; Raabe et al., 2005). Organic invertebrate remains, such as exoskeleton plates, mouthparts, or sclerotized resting stages, preserve well in lake sediments (Fig. 1). After the initial decomposition of degradable material, these structures can remain chemically stable for tens of thousands of years (Stankiewicz et al., 1997a) and, in exceptional cases, chitin may even preserve for millions of years in sediments (Stankiewicz et al., 1997b).

Stable isotope analysis of organic material produced in lakes and their surroundings provides information on past climate and ecosystem processes within lakes (e.g., Meyers and Lallier-Vergès, 2007). This information is used to establish linkages between climate changes and lake ecosystem history (Wigand et al., 2006). In the case of aquatic invertebrates, the stable isotopes of chitin in lake sediments provide unique insights into the paleoecology of aquatic ecosystems and can be applied to studies on past climate and aquatic food webs. This is due to the presence of chitin in the cuticles of most aquatic invertebrates, allowing for the reconstruction of past climate and aquatic food webs based on chitinous invertebrate fossils from lake sediments.

Figure 1: Examples of chitinous fossils produced in lakes and preserved in lake sediments: Head capsules of chironomid larvae (A, Polypedilum nubeculosum-type; D, Cricotopus), mandibles of larvae of other aquatic insects (B, Megaloptera; F, Ephemeroptera), a resting egg (ephippium) of a water flea (C, Cladocera), and a head capsule part (clypeus) of a caddisfly larva (E, Trichoptera).
