Science Highlights: Peatlands

Northern peatlands hold a large proportion of Northern Hemisphere land carbon (equivalent to as much as 1/3 of total global soil carbon) and are significant and active players in the global carbon cycle. An improved understanding of the controls and future dynamics of these carbon-rich ecosystems is possible from study of their Holocene history and previous carbon response to climate change. Peatland information relevant to Earth system dynamics includes the spatiotemporal pattern of expansion to the current ~4×10^9 km^2 occupied by northern peatlands, the variations in carbon accumulation at millennial and multi-centennial timescales, and the distribution of today’s 270-450 Pg (1 Pg = 1 gigatonne = 10^15 g) of peatland carbon as it relates to current climate.

Peatland expansion

Recently published datasets of basal 14C (radiocarbon) dates from extant peatlands indicate that northern peatlands have been sequestering atmospheric CO₂ and cycling land carbon at least since the early Holocene (e.g., Kylander et al., 2005; Shotton et al., 2001). There is also a clear need for interdisciplinary studies linking paleoenvironments, geochemistry and archeology (i.e., archival records), as well as atmospheric chemistry and transport modeling. There is tremendous opportunity to employ new analytical tools for the characterization of pollutant aerosols (e.g., Scanning electron microscope, Laser Ablation inductively coupled plasma mass spectrometry) as well as to investigate other elements that have been less studied (e.g., Rare Earth Elements, Platinum Group Elements) but may provide new insights into both nutrient input by natural atmospheric dusts during pre-anthropogenic times, and human impacts on the environment.

The northern peatland carbon pool and the Holocene carbon cycle

Understanding the role of peatlands in the Holocene carbon cycle will help predict the response of northern carbon stores to a changing climate.

Northern peatlands hold a large proportion of Northern Hemisphere land carbon (equivalent to as much as 1/3 of total global soil carbon) and are significant and active players in the global carbon cycle. An improved understanding of the controls and future dynamics of these carbon-rich ecosystems is possible from study of their Holocene history and previous carbon response to climate change. Peatland information relevant to Earth system dynamics includes the spatiotemporal pattern of expansion to the current ~4×10^9 km^2 occupied by northern peatlands, the variations in carbon accumulation at millennial and multi-centennial timescales, and the distribution of today’s 270-450 Pg (1 Pg = 1 gigatonne = 10^15 g) of peatland carbon as it relates to current climate.

Peatland expansion

Recently published datasets of basal 14C (radiocarbon) dates from extant peatlands indicate that northern peatlands have been sequestering atmospheric CO₂ and cycling land carbon at least since the early Holocene (Figs. 1 and 2; MacDonald et al., 2006; Gorham et al., 2007; Yu et al., 2009; Korhola et al., 2010). By 8 cal ka BP, peatlands had developed extensively across the continents in the Northern Hemisphere (Fig. 2e). This rapid wetland expansion contributed to the early Holocene rise and sustained peak in CH₄ concentrations after the Younger Dryas until about 8 cal ka BP (Fig. 2c; MacDonald et al., 2006), and
a subsequent expansion at 4 cal ka BP possibly contributed to the late Holocene CH₄ rise (Korhola et al., 2010). The carbon that accumulated on land as these early Holocene peatlands expanded could also have influenced the ~7 ppmv decrease in CO₂ at 11 - 8 cal ka BP (Fig. 2b) if this new carbon pool was large. A range of conservative estimates suggests that 29-98 Pg carbon existed as northern peat carbon by 8 cal ka BP (MacDonald et al., 2006; Yu et al., 2009) and this pool could have been substantially larger. These spatially referenced datasets of peat basal ages are large (Fig. 1) and continue to grow, providing additional opportunities for creative data-mining to address important Holocene carbon cycle questions.

Carbon accumulation
Numerous studies also report rates of Holocene carbon accumulation in northern peatlands. A characteristic feature of these data is a highly variable carbon accumulation history both within sites and between regions, indicating the complex balance between past plant growth and total Holocene losses via decomposition. However, a recent synthesis of available data from 33 Northern Hemisphere sites (Fig. 1) reveals high carbon accumulation during the early Holocene at many locations (Fig. 2d). For example, the greatest carbon accumulation appears to have occurred between 11 and 9 cal ka BP in Alaska, and between 10 and 8 cal ka BP at some sites in West Siberia (see Yu et al., 2009). Differences in the timing of peak carbon accumulation between regions were affected by delayed deglaciation, different timing of Holocene Thermal Maximum conditions, changes in the seasonality of insolation (Fig. 2a), and other landscape and atmospheric circulation factors. The available data suggest that an overall slowdown of carbon accumulation may have occurred after about 4 cal ka BP at many sites (Fig. 2d; Yu et al., 2009), which may be related to neoglacial cooling and permafrost formation in continental regions. Evidence for a renewed lateral expansion of peatlands in the mid-Holocene (Korhola et al., 2010) is seemingly at odds with evidence for a slowdown in vertical carbon accumulation after 4 cal ka BP (Fig. 2). Such a discrepancy suggests that the role of the large peat carbon pool in late Holocene CO₂ and CH₄ changes should be re-evaluated. Existing data are currently limited, but the wide distribution of peatlands across the Northern Hemisphere provides the possibility for much more information and a better understanding of ecosystem

Figure 1: Spatial pattern of the age of peatland establishment across the northern high latitudes showing basal radiocarbon ages (circles; n = 2380 IntCal04-calibrated ages; MacDonald et al., 2006; Gorham et al., 2007), IDW-interpolated (inverse distance weighted) surface of basal ages and the generalized pattern of establishment within 50 km of the distribution of boreal/taiga peatlands (colored shading), the location of carbon accumulation sites in Figure 2d (orange squares), and in Figure 3a (West Siberia, purple squares). Figure modified from Yu et al., 2009. Letters correspond to the location of photos to the right of the map.

Figure 2: Holocene timing of peatland establishment and carbon accumulation compared to variations in northern insolation and atmospheric CH₄ and CO₂. A) Winter (Dec) vs summer (June) insolation difference from the present (Berger and Loutre, 1991; stippled bands indicate insolation between 40 and 80°N). B) Atmospheric CO₂ recorded in EPICA Dome C Antarctic ice core (red circles; Mannin et al., 2001; Fluckiger et al., 2002). C) Atmospheric CH₄, recorded in Greenland (green circles; GISP2, Brook et al., 2000) and Antarctica (blue circles; EPICA Dome C; Mannin et al., 2001; Fluckiger et al., 2002). D) Composite curve of time-weighted mean (± SE) carbon accumulation at 33 sites in 1 ka bins (Yu et al., 2009). E) Occurrence frequency of the radiocarbon age of basal peat deposits (1-sigma age ranges) on each of the northern continents (MacDonald et al., 2006). The rapid early Holocene expansion of northern peatlands between about 11 and 8 cal ka BP is coincident with high carbon accumulation rates at many sites. This period of rapid peatland expansion and accumulation during the summer insolation maximum may have contributed significantly to the early Holocene rise in CH₄ and the slowdown and decrease in CO₂. Figure modified from MacDonald et al., 2006 and Yu et al., 2009.
Science Highlights: Peatlands

Climate Anomaly and the Little Ice Age. The response of land carbon to the relatively scant, but would provide insight into the nial variations in carbon dynamics are still such high-quality data for multi-centen and the influence of hydrological change. on both plant growth and soil respiration, influence of temperature, a direct control on carbon accumulation rate changes over (Fig. 3a). Developing reconstructions of carbon accumulation rate changes over the last 2 ka (7 to 88 kg m⁻²), and a pattern between sites that deviates from the pattern of total Holocene carbon accumulation (Beilman et al., 2009). This mismatch suggests that peatlands that were substantial carbon sinks during the early and mid-Holocene have not necessarily been the location of greatest carbon accumulation in the recent past. On the other hand, a strong north-south trend is evident that is positively correlated with mean annual temperature (Beilman et al., 2009) and growing season warmth (Fig. 3a). Developing reconstructions of carbon accumulation rate changes over the recent past could help tease apart the influence of temperature, a direct control on both plant growth and soil respiration, and the influence of hydrological change. Such high-quality data for multi-centennial variations in carbon dynamics are still scant, but would provide insight into the response of land carbon to the relatively well-studied climates of the Medieval Climate Anomaly and the Little Ice Age.

These data and analyses would provide a useful constraint on understanding the relationship between climate and CO₂, see Cox and Jones, 2008).

Peatland carbon and modern climate

Knowing the current climate domain of today’s northern carbon pools is relevant to predicting their fate in the face of global change. Northern peatland carbon typically occurs where annual mean temperatures are between -12° and 5°C and annual precipitation is between 200 and 1000 mm (Fig. 3b). However, many important regional differences are evident. Considering carbon-rich regions, the peatlands of West Siberia and the Mackenzie River Basin experience mean annual temperatures 7°C colder than those in the Hudson Bay Lowland. The warmest peatlands in these three regions (between -2 and 2°C) receive very different precipitation inputs, with southern West Siberia and southern Mackenzie peatlands receiving half as much annual precipitation as their warm counterparts in the southern Hudson Bay region (Fig 3b; Yu et al., 2009).

In this way, regional differences in the response of northern carbon were likely important in the Holocene carbon cycle, and will likely be important in future carbon dynamics. The further application of this kind of climate envelope analysis, and its potential combination with process modeling, provides another opportunity to better understand the possible trajectories in different regions of this very large terrestrial carbon pool.
